Architecture-based Rigorous System Design: An Airplane Engine Control Software Case Study

No Author Given

No Institute Given

Abstract. In this case study, we apply architecture-based rigorous system design approach to the control software of the airplane engine controller. Rigorous system design refers to a formal model-based process that leads from requirements to correct implementations. Architectures are a means for ensuring global coordination properties of system models and thus, achieving design correctness by construction. We implement the architecture diagrams for airplane engine control software in the Behavior-Interaction-Priority (BIP) component-based framework. We show how to obtain a system model by applying architectures to a set of atomic components. We also perform deadlock freedom analysis of the resulting system model by using the BIP tool-set and additionally validation analysis of our approach by using nuXmv model checker to verify that the safety properties enforced by the architecture are indeed satisfied.

1 Introduction

Design, manufacture and verification of large scale reliable hardware/software systems (e.g. cyber-physical systems) remains a grand challenge in system design automation [10]. To address this challenge, the rigorous system design methodology [9]. Rigorous system design can be understood as a formal, accountable and coherent process for deriving correct and trustworthy system implementations from high-level specifications. The essential safety properties of the design are guaranteed at the earliest possible design phase by applying algorithmic verification to the system model, and then the system implementation is automatically generated by a sequence of property preserving model transformations, progressively refining the model with details specific to the target platforms.

The architecture-based design approach consists of the three stages. First, architecture styles relevant for the application domain are identified and formally modelled. Ideally, this stage is only realised once for each application domain. The remaining stages are applied for each system to be designed. In the second design stage, requirements to be satisfied by the system are analysed and formalised, atomic components realising the basic functionality of the system are designed (components previously designed for other systems can be reused) and used as operands for the application of architectures instantiated from the styles defined in the first stage. The choice of the architectures to apply is driven by the requirements identified in the second stage. Finally, the resulting system is checked for deadlock-freedom. Properties, which are not enforced by

construction through architecture application, must be verified a posteriori. In this case study, we illustrate all steps of this process, except the requirement formalisation.

The Behavior-Interaction-Priority (BIP) framework [2] is proposed as a component-based system design framework, which comes with a formal language with well-defined semantics and a tool chain supporting rigorous system design process. The BIP language offers a three-layered modeling mechanism for constructing complex system behavior and architectures [6], i.e., Behavior, Interaction, and Priority. Behavior is characterized by a set of components, which are formally defined as automata extended with linear arithmetic. Interaction specifies the multiparty synchronization of components, among which data transfer may take place. Priority can be used to schedule the interactions or resolve conflicts when several interactions are enabled simultaneously. The key insight underlying this three-layered modeling mechanism is the principle of separation of concerns, that is, system computation is captured by a set of components, and system coordination is modeled by interaction and priority.

BIP framework advocates component-based design of correct-by-construction applications. It provides a simple, but powerful mechanism for the coordination of concurrent components by superposing three layers. First, component behaviour is described by Labelled Transition Systems (LTS) having transitions labelled with ports. Ports form the interface of a component and are used to define its interactions with other components. Second, interaction models, i.e. sets of interactions, define the component coordination. Interactions are sets of ports that define allowed synchronizations between components. An interaction model is defined in a structured manner by using connectors. Third, priorities are used to impose scheduling constraints and to resolve conflicts when multiple interactions are enabled simultaneously.

The BIP tool chain supports both algorithmic verification and testing of high-level system designs [3, 4, 8] and automatic system synthesis of low-level implementations from high-level system designs [5]. In practice, BIP has been actively used in several applications [1, 7].

The rest of the paper is structured as follows. In Section ?? and Section ??, we introduce the preliminaries and the BIP modeling language. In Section ?? and Section ??, we review the most related works and draw some conclusions and outline directions for future work.

2 Architectures in BIP

We use architecture diagrams [] to model the architecture styles in BIP. An architecture diagram consists of a set of component types, with associated cardinality constraints representing the expected number of instances of each component type and a set of connector motifs. Connector motifs, which define sets of BIP connectors, are non-empty sets of port types, each labelled as either a trigger or a synchron. Each port type has a cardinality constraint representing the expected number of port instances per component instance and two additional constraints: multiplicity and degree, represented as a pair $m : d$. Multiplicity constrains the number of instances of the port type that must participate in a connector defined by the motif; degree constrains the number of connectors attached to any instance of the port type.

In this section, we present the BIP model with multiparty synchronization and data transfer. A BIP model is a parallel composition of a set of components. A BIP component is formally defined as an automaton extended with linear integer arithmetic as follows.

Definition 1 (BIP component). *Given a finite set of variables \mathbb{V} , a BIP component is defined as a tuple $B = \langle \mathbb{V}, \mathbb{L}, \mathbb{P}, \mathbb{E}, \ell \rangle$, where 1. \mathbb{L} is a finite set of control locations; 2. \mathbb{P} is a finite set of communication ports; 3. $\mathbb{E} \subseteq \mathbb{L} \times \mathbb{P} \times \mathcal{F}_{\mathbb{V}} \times \mathcal{E}_{\mathbb{V}} \times \mathbb{L}$ is a finite set of transition edges extended with guards in $\mathcal{F}_{\mathbb{V}}$ and operations in $\mathcal{E}_{\mathbb{V}}$; 4. $\ell \in \mathbb{L}$ is an initial control location.*

Transition edges in a component are labeled by ports, which form the interface of the component. We assume that, from each control location, every pair of outgoing transitions have different ports, and the ports of different components are disjoint. In other words, transitions with the same ports in the component are not enabled simultaneously. Given a component violating such assumptions, one can easily transform it into the required form by renaming the ports, while retaining the BIP expressiveness power. To ease the presentation, we denote in the sequel the id of the unique component where port p is defined by $id(p)$.

We denote by $\mathcal{B} = \{B_i \mid i \in [1, n]\}$ a set of components. In BIP, coordinations of components are specified by using interactions.

Definition 2 (Interaction). *An interaction for \mathcal{B} is a tuple $\gamma = \langle g, \mathcal{P}, f \rangle$, where $g \in \mathcal{F}_{\mathbb{V}}$, $f \in \mathcal{E}_{\mathbb{V}}$ and $\mathcal{P} \subseteq \bigcup_{i=1}^n \mathbb{P}_i$, $\mathcal{P} \neq \emptyset$, and for all $i \in [1, n]$, $|\mathcal{P} \cap \mathbb{P}_i| \leq 1$.*

Intuitively, an interaction defines a guarded multiparty synchronization with data transfer: when the guard g of an interaction \mathcal{P} is enabled, then the data transfer specified by f can be executed, and after that the transitions labelled by the ports in γ can be taken simultaneously. We denote by Γ a finite set of interactions. A BIP model is constructed by composing a number of components with interactions.

Definition 3 (BIP Model). *A BIP model \mathcal{M}_{BIP} is a tuple $\langle \mathcal{B}, \Gamma \rangle$, where \mathcal{B} is a finite set of components, and Γ is a finite set of interactions for \mathcal{B} .*

We do not take priority into account in this paper, as in the previous work [3, 8], since adding priority will not introduce any errors. If a model without priority is safe, then after adding priority constraints it remains safe. We use a simple mutual exclusion protocol to illustrate BIP.

A state of a BIP model is a tuple $c = \langle \langle l_1, \mathbf{V}_1 \rangle, \dots, \langle l_n, \mathbf{V}_n \rangle \rangle$, where for all $i \in [1, n]$, $l_i \in \mathbb{L}_i$ and \mathbf{V}_i is a valuation of \mathbb{V}_i . A state c_0 is initial if for all $i \in [1, n]$, $l_i = \ell_i$ and \mathbf{V}_i is the initial valuation of \mathbb{V}_i . A state c is an error if for some $i \in [1, n]$, l_i is an error location. We say an interaction $\gamma \in \Gamma$ is enabled on a state c if for every component $B_i \in \mathcal{B}$, such that $\gamma \cap \mathbb{P}_i \neq \emptyset$, there is an edge $\langle l_i, \gamma \cap \mathbb{P}_i, g_i, f_i, l'_i \rangle \in \mathbb{E}_i$ and $\mathbf{V}_i \models g_i$. The labeled transition system semantics of a BIP model is defined as follows.

Definition 4 (BIP operational semantics). *Given a BIP model $\mathcal{M}_{\text{BIP}} = \langle \mathcal{B}, \Gamma \rangle$, its operational semantics is defined by a labeled transition system $\mathcal{T}_{\text{BIP}} = \langle \mathcal{C}, \Sigma, \mathcal{R}, \mathcal{C}_0 \rangle$, where*

1. \mathcal{C} is the set of states,
2. $\Sigma = \Gamma$,
3. \mathcal{R} is the set of transitions, and we say that there is a transition from a state c to another state c' , if there is an interaction γ such that,
 - (a) γ is enabled in c ;
 - (b) for all $B_i \in \mathbb{B}$ such that $\gamma \cap \mathbb{P}_i \neq \emptyset$, there is an edge $\langle l_i, \gamma \cap \mathbb{P}_i, g_i, f_i, l'_i \rangle \in \mathbb{E}_i$, then $\mathbf{V}'_i = \mathbf{V}_i[\mathbb{V}/f_i(\mathbb{V})]$;
 - (c) for all $B_i \in \mathbb{B}$ such that $\gamma \cap \mathbb{P}_i = \emptyset$, $l'_i = l_i$ and $\mathbf{V}'_i = \mathbf{V}_i$.
4. \mathcal{C}_0 is the set of initial states.

In this paper, we do not use temporal logics to specify safety properties, but recognize a set of locations as error locations. A BIP model is safe if no error states are reachable. Notice that any safety property can be encoded as a reachability problem by necessarily creating additional components.

3 Case study

In this section, we will introduce an airplane engine control software case study. Due to its huge scale, we choose one of its subsystem, the PLA signal processing system, as representative. We will give an informal description of it, focusing on its functional structure, properties and conditional constraints. To perform deadlock freedom analysis, we generate a formal system model in BIP. Finally, we provide model verification and validation for the system above.

3.1 Informal description

The Power Level Angle(PLA) signal processing system is part of the Full Authority Digital Engine Control System(FADEC), which provides engine control during flight to achieve stable and transient engine characteristics. The purpose of PLA signal processing system is to convert the obtained throttle stick signal value into the original throttle stick angle value and judge it. If it is judged that there is no fault, then it will return the corresponding value of the PLA signal after processing and set a fault signal to invalid, representing that the system has no PLA signal fault in current period. Otherwise it will return the fault information and set the fault signal to valid. The flow chart of PLA signal processing is roughly as follows:

As shown in figure ?, there are three modules in the system. PLA signals will first undergo a BIT Diagnosis module, then be calibrated and converted into physical quantities. After the Extremum and Slope Diagnosis module, it will finally generate the PLA fault signal for output.

The Built-in Test(BIT) refers to the detection and monitoring of the system and its own equipment. In the PLA signal processing system model, the BIT Diagnosis realizes the analog quantity, or periodic fault detection of circuits such as fault location and processing based on the diagnosis results.

The calibration conversion module's function is to collect the signal from signal collector. The arriving signal will be converted to the corresponding engineering value by means of a calibration curve or an index table.

An Extremum/Slope Diagnosis module contains extremum diagnosis and slope diagnosis. The function of extremum diagnosis is to judge whether the current signal is in valid range since the PLA signal processing system cannot handle illegal data. The function of slope diagnosis is to give the constraint of the magnitude of the change between the two adjacent signals.

The three modules introduced above work together for giving a credible output signal. In the next chapter, we will translate this informal model to formal BIP model for further verification and validation.

3.2 Formal system model in BIP

We design our PLA Signal Processing System's BIP model through a combination between series of BIP components with BIP interactions. The block diagram for our system is shown in figure 1.

Fig. 1. Architecture of System

The atomic components of our system are *TaskAtom t1*, *CalibrationAtom c1* and several atomics in *p1* and *c2*. For each atomic component, we specify its ports, variables and behavior.

An atomic model of *Task* is shown in figure 2, which can be used as a function of message sender in *System*. In the graphical notation, the atomic is initialized to *Wait*, and the following three transitions are driven by corresponding events: *produce*, *send-BIT* and *sendMean*, which represents three corresponding ports in the atomic. For instance, whenever the current state is at *Start*, the port *sendBIT* will be activated and the transition will be executed once the event *sendBIT* is done.

In our design, the BIT Diagnosis is a subsystem of PLA signal processing system. Its architecture is shown in figure 3. In the graphical notation, the three atomic component instances *p1*, *p2* and *p3* receive BIT signal through port *receiveBIT*, a connector distributes the signal to these components and another connector merges their output and sends it to the an instance of *Decider* component. The BIP description of *BIT Diagnosis* is shown below:

```
compound BITCompound_P1
  component BITAtom_enc enc
```

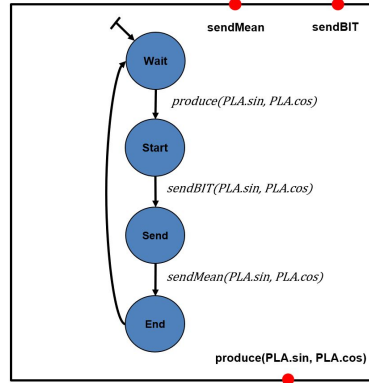

Fig. 2. The Task Component

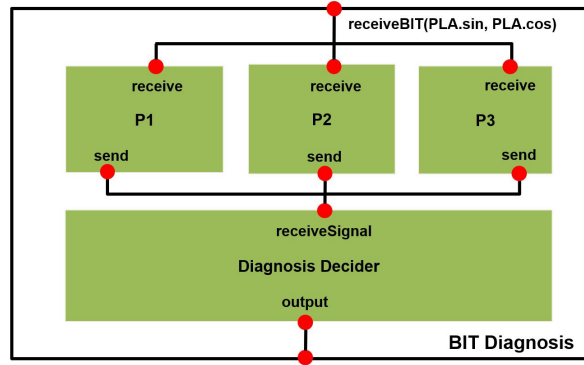

Fig. 3. Architecture of BIT Diagnosis

```

component BITAtom.sin sin
component BITAtom.cos cos
component BITAtom.Decider d

connector ThreeToOne o(enc.sendBIT, sin.sendBIT, cos.sendBIT, d.receiveSignal)
connector Merge m(enc.receiveBIT, sin.receiveBIT, cos.receiveBIT)

export port m.Merged.Signal as receiveBIT
export port d.output as sendBIT
end
  
```

In our system, atomic component is considered as the smallest unit of the architecture, while in the combination of several components, such as our BIT Diagnosis module, we have to ensure that the output of three components can simultaneously reach the connector, otherwise it will fall into deadlock status. To avoid this problem,

the three atomic components are designed homogeneous, we take one of these three components, *BITAtom_enc p1*, as an example, its ports and behavior is shown below:

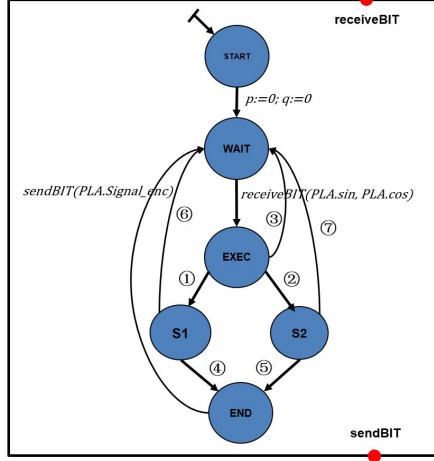

Fig. 4. Architecture of BIT Diagnosis P1

Table 1. Transitions of P1

Transition	Guard	Action
1	$PLA.sin < 500 \wedge PLA.cos < 500$	$p := p + 1; q := 0$
2	$PLA.sin \geq 500 \wedge PLA.cos \geq 500$	$p := 0; q := q + 1$
3	$PLA.sin \geq 500 \oplus PLA.cos \geq 500$	$p := 0; q := 0$
4	$p \geq 5$	$PLA.Signal_enc := 1$
5	$q \geq 5$	$PLA.Signal_enc := 0$
6	$p < 5$	null
7	$q < 5$	null

During execution, we consider a WAIT to WAIT transition set as a cycle. In each cycle, we ensure that an *sendBIT* event will be activated to avoid the system falling into deadlock status. With the combination of connector, *P1* gives a synchronous output together with other two atomic component instances. We define two variables *p* and *q* as counters to control the vary of signal. Their constraint indicates that for every continuous five cycles, the system does a setting and gives a corresponding output through port *sendBIT*.

To give a formal proof of its safety and effectiveness. The verification and validation of the system above will produced in the next chapter.

3.3 Model verification and validation

4 Related work

In the BIP framework, DFinder [3] is a dedicated tool for invariant generation and deadlock-freedom detection. DFinder computes the system invariant in a compositional manner: it first computes a component invariant over-approximating the reachable states of each component and then computes an interaction invariant over-approximating the global reachable states. The system invariant is then the conjunction of all component invariants and the interaction invariant. Though being scalable for large system models, DFinder does not handle system models with data transfer, which hampers the practical application of DFinder and of the BIP framework, since data transfer is necessary and common in the design of real-life systems (e.g. message passing). Besides, it is not clear in DFinder how to refine the abstraction automatically when the inferred invariant fails to justify the property.

A compositional encoding of BIP into nuXmv and an efficient instantiation of Explicit Scheduler Symbolic Thread (ESST) framework for BIP have been presented in [4]. The encoding into nuXmv allows one to exploit the state-of-the-art verification techniques to verify BIP models. The ESST based technique encodes the components as preemptive threads with predefined primitive functions and utilizes a dedicated stateful BIP scheduler to orchestrate the abstract reachability analysis of the components. The scheduler interacts with components via primitive functions, and also respects BIP operational semantics. Moreover, partial order reduction techniques are applied in the scheduler to reduce the states of scheduler.

In [8], we present a lazy predicate abstraction technique for BIP, and we also propose a novel reduction technique called simultaneous set reduction, which is further combined with lazy abstraction to reduce the search space of the abstract reachability analysis.
